Expectations, Credibility, and Time-Consistent Monetary Policy

by Peter N. Ireland

This paper addressses the problem of multiple equilibria in a model of time-consistent monetary policy. It suggests that this problem originates in the assumption that agents have rational expectations and proposes several alternative restrictions on expectations that allow the monetary authority to build credibility for a disinflationary policy by demonstrating that it will stick to that policy even if it imposes short-run costs on the economy. Starting with these restrictions, the paper derives conditions that guarantee the uniqueness of the model's steady state; monetary policy in this unique steady state involves the constant deflation advocated by Milton Friedman.

Expectations, Credibility, and Time-Consistent Monetary Policy

1. Introduction

Kydland and Prescott (1977) identify the inflationary bias that results when a monetary authority cannot precommit to a policy rule. In their model, the monetary authority desires to reduce unemployment and can do so by creating surprise inflation. Private agents with rational expectations recognize that the monetary authority has this incentive to inflate, however, and build the effects of that inflation into their decisions. In equilibrium, therefore, unemployment is no lower than it would otherwise be; the monetary authority's discretionary policy leads only to excessive inflation. This is the classic time-consistency problem for monetary policy.

Barro and Gordon (1983) extend Kydland and Prescott's (1977) work, demonstrating that reputational considerations can reduce the inflationary bias stemming from the time-consistency problem. In particular, Barro and Gordon consider cases in which inflationary expectations remain low so long as the monetary authority has kept inflation low in the past but jump higher for a period of time should the government deviate from its low-inflation policy. The costs imposed by this episode of higher inflationary expectations induce the monetary authority to adhere to the low-inflation policy.

Barro and Gordon (1983) also recognize, however, that these trigger-like reputational mechanisms support a multiplicity of equilibria featuring a range of inflation rates. In fact, this large number of possible outcomes expands still further when more general approaches are taken to characterize the set of reputational equilibria. Ireland (1996), for instance, uses methods developed by Chari and Kehoe (1990) and Stokey (1991) to trace out the entire set of time-consistent monetary policies in a version of the Barro-Gordon model; policies in this set allow any rate of inflation to arise in equilibrium.

As noted by Stokey (1991), whether this multiplicity of equilibria represents a serious problem for models of time-consistent monetary policy depends partly on how these models are interpreted. If, for example, one interprets the models

as describing a positive theory of monetary policy, then one might even regard the multiplicity as a virtue: from this perspective, the theory explains both why central bankers in low-inflation countries choose to maintain their reputations as inflation-fighters and why central bankers in high-inflation countries find it so difficult to bring inflation down. If one interprets the models as offering a normative theory, however, then one must admit that the multiplicity is a shortcoming, for the theory provides no guidance as to how a central banker who is stuck in a high-inflation equilibrium might steer the economy towards a preferred, low-inflation equilibrium.

This paper takes the normative view and addresses the multiplicity of equilibria as a problem for models of time-consistent monetary policy. The paper suggests that this problem originates in the assumption, made throughout the literature, that agents have rational expectations. As emphasized by Sargent (1993), the rational expectations assumption becomes, in many settings, a convenient and powerful tool for sharpening the predictions of economic theory. In reputational models of time-consistent monetary policy, however, the rational expectations assumption may be less appropriate. In the trigger-strategy equilibria studied by Barro and Gordon (1983), for instance, the rational expectations assumption allows inflationary expectations to jump higher not just when the mon-

etary authority surprises the public by creating too much inflation but also when it surprises the public by attempting to disinflate; rational expectations provide no scope for the monetary authority to work inflationary expectations down by actually adopting and building credibility for a disinflationary program.

Thus, the analysis in this paper departs from the rational expectations assumption in three ways. First, the analysis requires expected inflation to move together with actual inflation: inflationary expectations may still rise if the monetary authority attempts to create surprise inflation, but they must begin to ease if the monetary authority attempts to disinflate. Second, and related, the analysis requires the expected rate of inflation to converge to the actual rate of inflation, provided that the monetary authority acts to keep inflation constant for a sufficient length of time; inflationary expectations have Cho and Matsui's (1995) inductive property. Together, these first two restrictions allow the monetary authority to build credibility for a disinflationary policy, in a manner suggested by Taylor (1982) and McCallum (1995), by demonstrating that it will stick to that policy even if it imposes short-run costs on the economy. Third, and finally, the analysis requires inflationary expectations to be formed as continuously differentiable functions of past inflation rates. Rogoff (1989) suggests that by restricting the extent to which expected inflation can jump in response to a change in ac-

tual inflation, the multiplicity of equilibria in models of time-consistent monetary policy might be reduced and, indeed, his conjecture proves useful here.

The paper imposes these three restrictions on private expectations in a model of time-consistent monetary policy developed in Ireland (1996), which unlike the original Barro-Gordon model, begins with a complete description of a general equilibrium environment featuring utility-maximizing households and profit-maximizing firms. This model draws a tight link between the government's objectives and those of the private sector: the monetary authority seeks to adopt a policy that maximizes a representative household's utility function. By identifying this welfare criterion for policy, the model facilitates the type of normative analysis performed here. The original Barro-Gordon model, in contrast, does not explicitly tie the government's objectives to the preferences of private agents, making a normative interpretation of its implications more difficult.

Starting with the three restrictions on expectations, the paper derives conditions that guarantee the uniqueness of the model's steady state; monetary policy in this unique steady state involves the constant deflation advocated by Friedman (1969). The paper goes on to present a pair of examples, in which the model is solved numerically. These examples show that when the economy begins away from its unique steady state, with a positive rate of inflation, the monetary

authority can implement a successful disinflationary program under which monetary policy is ultimately given by the Friedman rule. In both examples, however, output and employment fall in the short run as the monetary authority builds credibility for the optimal policy; in the second example, the monetary authority optimally smooths these short-run costs over time by taking a gradual approach to disinflation.

The paper is related to several lines of recent research. First, in the game theory literature, work following Rubinstein (1986) takes an approach similar to the one used here by showing that the introduction of boundedly rational agents reduces the number of equilibria in settings where a severe multiplicity arises under rational expectations. Similarly, in macroeconomics, Sargent (1993) discusses a number of models in which equilibria with strange or undesirable features appear under rational expectations but can be ruled out or replaced by more conventional outcomes when assumptions of bounded rationality are made instead. And in work that is most closely related to this, Cho and Matsui (1995) show how the number of equilibria in Stokey's (1991) model of time-consistent public policy can be reduced to one when agents are constrained to use inductive forecasting rules. But while some of Cho and Matsui's assumptions are weaker than those used here, their results apply only in the case of no discounting; the analysis performed here,

in contrast, allows private agents to discount future payoffs.

Work by Backus and Driffill (1985) and Barro (1986) also addresses the problem of multiple equilibria in models of time-consistent monetary policy. These authors modify the infinite-horizon Barro-Gordon model by making the horizon finite. They then assume that the monetary authority may be of two types, one that has the conventional objectives and the other that is more averse to inflation; private agents do not know the policymaker's true type. This variant of the model succeeds in identifying a unique equilibrium, in which the conventional policymaker chooses to keep inflation low in order to convince private agents that he is of the inflation-averse type. As noted by Blackburn and Christensen (1989), however, the assumption that policymakers may be of different types necessarily means that not all can share the private sector's objectives; since government and private objectives need not coincide, these models become difficult to interpret along normative lines. Furthermore, as noted by Rogoff (1989), the precise features of the unique equilibrium in these models depend crucially on the characteristics of the alternative policymaker that is introduced; by varying the preferences of the alternative type, a large number of equilibria can again be produced.

Finally, al-Nowaihi and Levine (1994) explore the implications of various equilibrium refinements in the Barro-Gordon model and succeed at identifying a

unique outcome that satisfies their chisel-proof criterion. But their analysis requires the private sector to act collectively; the uniqueness result need not extend to the case in which private agents operate in a decentralized, competitive environment where the coordination of their actions becomes difficult.

Thus, while some progress has been made at confronting the problem of multiple equilibria in models of time-consistent monetary policy, a full resolution of this problem has yet to be reached, leaving room for this paper's contribution to the literature.

2. The Model

2.1. The Economic Environment

The model resembles one developed in Ireland (1996). Household face cash-in-advance constraints on their purchases of consumption goods. These constraints give rise to an interest-elastic demand for real balances; expected inflation causes agents to inefficiently economize on their money holdings. Firms operate in monopolistically competitive markets and must set prices for their output one period in advance. Monopolistic competition implies that equilibrium output falls below its efficient level, while sticky prices allow unanticipated money to have real effects;

the monetary authority can push output closer to its efficient level by creating surprise inflation. Thus, the monetary authority faces a trade-off between the costs of expected inflation and the benefits of unexpected inflation; this trade-off gives rise to the time-consistency problem when the monetary authority cannot commit to a policy rule.

The economy consists of a representative household, a continuum of firms indexed by $i \in [0,1]$, and a monetary authority. Each firm produces a distinct, perishable consumption good. Hence, goods may also be indexed by $i \in [0,1]$, where firm i produces good i. Preferences and technologies display enough symmetry, however, to allow the analysis to focus on the activities of a representative firm, identified by the generic index i.

The monetary authority makes a lump-sum transfer $(x_t - 1)M_t^s$ to the representative household during each period $t = 0, 1, 2, ...$ Thus, the per-household money stock M_t^s at the beginning of period t obeys

$$M_{t+1}^s = x_t M_t^s,$$

for all $t = 0, 1, 2, ...,$ where a choice of nominal units yields the initial condition $M_0^s = 1$. Thus, if M_t denotes the money carried by the representative household

into period t, market clearing requires that $M_t = M_t^s$ for all $t = 0, 1, 2, \ldots$.

The representative household trades bonds as well as money. Bonds costing the household B_{t+1}/R_t dollars during period t return B_{t+1} dollars during period $t+1$, where R_t is the gross nominal interest rate between t and $t+1$. Bonds are available in zero net supply; hence, market clearing requires that $B_t = 0$ for all $t = 0, 1, 2, \ldots$.

2.2. The Timing of Events

As suggested above, the representative household enters period t with money M_t and bonds B_t. The representative firm enters period t having set a fixed nominal price $P_t(i)$ for its output.

At the beginning of period t, the representative household receives the nominal transfer $(x_t - 1)M_t^s$. Next, the household's bonds B_t mature, bringing its total money holdings to $M_t + (x_t - 1)M_t^s + B_t$. The household uses some of this cash to purchase new bonds at cost B_{t+1}/R_t and carries the rest into the goods market.

The description of goods production and trade draws on Lucas' (1980) interpretation of the cash-in-advance model. The representative household consists of two members: a shopper and a worker. During period t, the shopper purchases $c_t(i)$ units of each good i from firm i at its fixed nominal price $P_t(i)$, subject to

the cash-in-advance constraint

$$M_t + (x_t - 1)M_t^s + B_t - B_{t+1}/R_t \geq \int_0^1 P_t(i)c_t(i)di.$$

The worker, meanwhile, supplies $n_t(i)$ units of labor to each firm i. He receives the nominal wage W_t. The household's preferences are described by the utility function

$$\sum_{t=0}^{\infty} \beta^t [\ln(c_t) - n_t], \tag{1}$$

where $1 > \beta > 0$ and the composite goods c_t and n_t are defined by

$$c_t = \left[\int_0^1 c_t(i)^{(\theta-1)/\theta} di \right]^{\theta/(\theta-1)}$$

with $\theta > 1$ and

$$n_t = \int_0^1 n_t(i)di$$

for all $t = 0, 1, 2, ...$

The representative firm must sell output on demand at its fixed price $P_t(i)$ during period t. It produces this output, denoted $y_t(i)$, according to a linear technology that yields one unit of good i for every unit of labor input. After goods production and trade take place, the firm makes its wage payment and

distributes any profit as a dividend to the representative household. In light of the linear technology, this dividend $D_t(i)$ equals price minus wage times quantity sold:

$$D_t(i) = [P_t(i) - W_t]y_t(i).$$

At the end of period t, the representative firm sets its nominal price $P_{t+1}(i)$ for period $t+1$. The representative household uses its unspent cash and its wage and dividend receipts as sources of funds with which to accumulate the money M_{t+1} that it carries into period $t+1$; it faces the budget constraint

$$M_t + (x_t - 1)M_t^s + B_t + W_t n_t + \int_0^1 D_t(i)di \geq \int_0^1 P_t(i)c_t(i)di + B_{t+1}/R_t + M_{t+1}.$$

As a first step in characterizing an equilibrium for this economy, define $m_t = M_t/M_t^s$, $b_t = B_t/M_t^s$, $w_t = W_t/M_t^s$, $d_t(i) = D_t(i)/M_t^s$, and $p_t(i) = P_t(i)/M_t^s$. In terms of these scaled nominal variables, the representative household's budget and cash-in-advance constraints become

$$m_t + x_t - 1 + b_t + w_t n_t + \int_0^1 d_t(i)di \geq \int_0^1 p_t(i)c_t(i)di + b_{t+1}x_t/R_t + m_{t+1}x_t$$

and

$$m_t + x_t - 1 + b_t - b_{t+1}x_t/R_t \geq \int_0^1 p_t(i)c_t(i)di,$$

while the representative firm's dividend payment becomes

$$d_t(i) = [p_t(i) - w_t]y_t(i).$$

2.3. Household Optimization

During each period $t = 0, 1, 2, ...$, the representative household chooses sequences of current and future consumptions, labor supplies, and holdings of money and bonds to maximize its utility subject to its budget and cash-in-advance constraints. When it solves this optimization problem, the household knows the value $(x_t - 1)M_t^s$ of the current period's monetary transfer but must form expectations of money growth in all future periods. Thus, suppose that the household believes that with probability one, x_{t+j} will equal some constant z_{t+j}^t; then for $t = 0, 1, 2, ...$ and $j = 1, 2, 3, ...$, z_{t+j}^t denotes the household's expectation during period t of money growth during period $t + j$, while for $j = 0$, $z_{t+j}^t = z_t^t = x_t$.

During each period $t = 0, 1, 2, ...$, therefore, the household chooses sequences

$\{c_{t+j}^t\}_{j=0}^{\infty}$, $\{c_{t+j}^t(i)\}_{j=0}^{\infty}$, $\{n_{t+j}^t\}_{j=0}^{\infty}$, $\{m_{t+j+1}^t\}_{j=0}^{\infty}$, and $\{b_{t+j+1}^t\}_{j=0}^{\infty}$ to maximize

$$\sum_{j=0}^{\infty} \beta^j [\ln(c_{t+j}^t) - n_{t+j}^t] \tag{2}$$

subject to the constraints

$$\left[\int_0^1 c_{t+j}^t(i)^{(\theta-1)/\theta} di\right]^{\theta/(\theta-1)} \geq c_{t+j}^t, \tag{3}$$

$$\begin{aligned} & m_{t+j}^t + z_{t+j}^t - 1 + b_{t+j}^t + w_{t+j}^t n_{t+j}^t + \int_0^1 d_{t+j}^t(i)di \\ \geq \quad & \int_0^1 p_{t+j}^t(i)c_{t+j}^t(i)di + b_{t+j+1}^t z_{t+j}^t / R_{t+j}^t + m_{t+j+1}^t z_{t+j}^t, \end{aligned} \tag{4}$$

and

$$m_{t+j}^t + z_{t+j}^t - 1 + b_{t+j}^t - b_{t+j+1}^t z_{t+j}^t / R_{t+j}^t \geq \int_0^1 p_{t+j}^t(i)c_{t+j}^t(i)di \tag{5}$$

for all $j = 0, 1, 2, ...$, where w_{t+j}^t, $d_{t+j}^t(i)$, $p_{t+j}^t(i)$, and R_{t+j}^t denote the household's expectations of w_{t+j}, $d_{t+j}(i)$, $p_{t+j}(i)$, and R_{t+j} during period t, and where $d_t^t(i) = d_t(i)$, $w_t^t = w_t$, $p_t^t(i) = p_t(i)$, and $R_t^t = R_t$.

In equilibrium, the values of c_t^t, $c_t^t(i)$, n_t^t, m_{t+1}^t, and b_{t+1}^t that solve this problem become the actual values of c_t, $c_t(i)$, n_t, m_{t+1}, and b_{t+1} chosen by the household

during period t. Thus, part 1 of the appendix demonstrates that

$$c_t(i) = (z_t^t/p_t)[p_t(i)/p_t]^{-\theta}, \tag{6}$$

$$c_t = z_t^t/p_t, \tag{7}$$

$$w_t = z_t^t z_{t+1}^t/\beta, \tag{8}$$

and

$$R_t = z_{t+1}^t/\beta, \tag{9}$$

where the scaled nominal price index p_t is defined by

$$p_t = \left[\int_0^1 p_t(i)^{1-\theta} di\right]^{1/(1-\theta)} \tag{10}$$

for all $t = 0, 1, 2, ...$

2.4. Firm Optimization

At the end of period $t-1$, the representative firm must set its fixed nominal price $P_t(i)$ for period t. When it chooses this price, it knows the value of the money stock M_t^s. Hence, the firm can also be depicted as choosing a scaled nominal price

$p_t(i)$ for period t.

Looking ahead to period t, the firm knows that it will be required to satisfy the representative household's demand $c_t(i)$ for good i, described by (6). The firm also knows that in order to produce this output, it will have to hire labor at the scaled nominal wage w_t, given by (8). Thus, at the end of period $t-1$, the firm must form expectations of the household's expectations z_t^t and z_{t+1}^t. Here, it is assumed that the firm's expectations are consistent with those of the household, so that the firm's expectation of z_t^t during $t-1$ is given by z_t^{t-1}, while its expectation of z_{t+1}^t is given by z_{t+1}^{t-1}.

Thus, the firm chooses $p_t(i)$ at the end of period $t-1$ to maximize its expected scaled nominal dividend

$$d_t^{t-1}(i) = (z_t^{t-1}/p_t)[p_t(i) - z_t^{t-1}z_{t+1}^{t-1}/\beta][p_t(i)/p_t]^{-\theta}.$$

The solution to this problem implies that

$$p_t(i) = [\theta/(\theta-1)](z_t^{t-1}z_{t+1}^{t-1}/\beta). \tag{11}$$

Since the right-hand side of (11) does not depend on i, all firms $i \in [0,1]$ set the

same price in equilibrium; hence, (10) implies

$$p_t = [\theta/(\theta - 1)](z_t^{t-1} z_{t+1}^{t-1}/\beta) \tag{12}$$

for all $t = 0, 1, 2, ...$

2.5. Equilibrium

Substituting the solutions for $p_t(i)$ and p_t given by (11) and (12) into the solutions for $c_t(i)$ and c_t given by (6) and (7) and using the definition $z_t^t = x_t$ reveals that $c_t(i) = c_t$ for all $i \in [0, 1]$, where

$$c_t = \beta[(\theta - 1)/\theta](x_t/z_t^{t-1})(1/z_{t+1}^{t-1}) \tag{13}$$

for all $t = 0, 1, 2, ...$ The equilibrium conditions $c_t(i) = y_t(i) = n_t(i)$ for all $i \in [0, 1]$ then imply that $n_t = c_t$, so that (13) also describes the representative household's total labor supply during each period $t = 0, 1, 2, ...$ Hence, (13) provides solutions for aggregate consumption, output, and employment.

Equation (13) highlights the source of the time-consistency problem for monetary policy in this model. Since firms set prices one period in advance, the monetary authority can increase output and employment by setting actual money

growth x_t above its expected value z_t^{t-1}. But since households face cash-in-advance constraints, they inefficiently economize on their real balances by substituting out of market activity and into leisure in the face of higher expected inflation. Thus, output and employment fall when z_{t+1}^{t-1} rises.

3. Expectations, Credibility, and Time-Consistent Monetary Policy

According to (13), consumption, output, and employment during each period $t = 0, 1, 2, ...$ depend not only on actual money growth during period t, but also on private agents' expectations during period $t-1$ of money growth during periods t and $t+1$. Hence, to complete the description of an equilibrium for this economy, it is necessary to specify how agents form these expectations.

The typical approach taken in the literature on time-consistent monetary policy assumes that agents have rational expectations or, in cases like this where there are no sources of uncertainty, perfect foresight. With perfect foresight, agents' expectations of money growth during periods t and $t+1$ coincide with the actual values of money growth during these periods, so that $z_t^{t-1} = x_t$ and $z_{t+1}^{t-1} = x_{t+1}$ for all $t = 0, 1, 2, ...$

As emphasized by Chari and Kehoe (1990) and Stokey (1991), one must consider two distinct environments in which optimal policy may be formulated under rational expectations. In the first environment, the government has access to a technology that allows it to announce, at the beginning of period $t = 0$, a sequence $\{x_t\}_{t=0}^{\infty}$ of planned money growth rates and to commit to actually following that plan in all future periods. Ireland (1996) shows that in this case with commitment, the optimal policy in the model considered here sets $x_t = \beta$ for all $t = 0, 1, 2, ...$, as called for by Friedman (1969), to make the net nominal interest rate $R_t - 1$ constant and equal to zero.

In the second environment, the government lacks a commitment technology. In this environment, the government can still announce a sequence of planned money growth rates $\{x_t\}_{t=0}^{\infty}$ at the beginning of period $t = 0$, but is free to rechoose the sequence $\{x_{t+j}\}_{j=0}^{\infty}$ at the beginning of each subsequent period $t = 1, 2, 3, ...$ Thus, the government has no mechanism for committing itself to a future plan for monetary policy and can instead be viewed as choosing a value for x_t at the beginning of each period $t = 0, 1, 2, ...$

In the case without commitment, the time-consistency problem arises. The benefits from creating surprise inflation provide the monetary authority with an incentive to choose a rate of money growth that is higher than expected in each pe-

riod. But with rational expectations, private agents recognize that the monetary authority has this incentive and adjust their behavior accordingly. In equilibrium, therefore, the time-consistency problem may lead to the outcome first described by Kydland and Prescott (1977), in which the monetary authority attempts to increase output and employment by creating surprise inflation but finds that its efforts lead only to a higher rate of expected inflation.

By applying methods developed by Chari and Kehoe (1990) and Stokey (1991) to the model used here, Ireland (1996) shows that there are, in fact, many possible outcomes in the case where the monetary authority lacks a commitment technology and agents have rational expectations. These outcomes can all be supported in equilibria where private expectations display an extreme form of trigger-like behavior: a single deviation by the monetary authority away from its proposed policy causes expected inflation to jump permanently to a very high level. In one such equilibrium, policy follows the Friedman (1969) rule, even without commitment: the single period gain from setting x_t above β is more than offset by the costs of higher expected inflation forever after. But these trigger-strategy equilibria also support many other outcomes with higher rates of inflation.

Thus, to reduce the number of equilibria in this model of time-consistent monetary policy, suppose that instead of having perfect foresight, agents must form

their expectations in period $t-1$ of money growth during periods t and $t+1$ as stationary functions of actual money growth during periods $t-1$ through $t-N$, so that

$$z_t^{t-1} = \psi^1(x_{t-1}, x_{t-2}, ..., x_{t-N}) \tag{14}$$

and

$$z_{t+1}^{t-1} = \psi^2(x_{t-1}, x_{t-2}, ..., x_{t-N}) \tag{15}$$

for all $t = 0, 1, 2, ...$, where $N < \infty$ is a positive integer and where the expectations functions $\psi^1 : \mathbf{R}_{++}^N \rightarrow \mathbf{R}_{++}$ and $\psi^2 : \mathbf{R}_{++}^N \rightarrow \mathbf{R}_{++}$ satisfy the following three restrictions:

(R1) ψ^1 and ψ^2 are non-decreasing in each of their arguments.

(R2) For all $x \in \mathbf{R}_{++}$, $\psi^1(x, x, ..., x) = \psi^2(x, x, ..., x) = x$.

(R3) ψ^1 and ψ^2 are continuously differentiable on $\mathbf{R}_{++}^N$.

Restriction (R1) requires the expected rate of future money growth to move together with the actual rate of money growth; it still allows inflationary expectations to rise if the monetary authority creates too much actual inflation, but also implies that inflationary expectations will begin to ease if the monetary

authority acts to bring actual inflation down. Restriction (R2) requires that expectations have Cho and Matsui's (1995) inductive property: if the monetary authority holds money growth constant at any rate x for at least N consecutive periods, then private agents will come to expect that it will continue to hold money growth constant at x. Thus (R1) and (R2) allow the monetary authority to build credibility for a disinflationary policy by simply adopting and following that policy for a sufficient length of time, as suggested by Taylor (1982) and McCallum (1995). The rational expectations assumption, in contrast, may make it impossible for the monetary authority to build credibility; the trigger-like mechanisms used to support the multitude of equilibria in Ireland (1996), for instance, require expected inflation to rise even when the monetary authority surprises the public by attempting to lower the current inflation rate. Restriction (R3) limits the extent to which expectations of future monetary growth can jump following any unexpected change in policy; Rogoff (1989) suggests that the number of equilibria in models of time-consistent monetary policy might be reduced under such a restriction. Expectations functions satisfying restrictions (R1)-(R3) also appear throughout the literature on temporary general equilibrium theory; see, for example, Fuchs and Laroque (1976), Fuchs (1979), Tillmann (1983), and Grandmont and Laroque (1986).

Equation (9) links the gross nominal interest rate to the expected future money growth rate via $R_t = z_{t+1}^t/\beta$. If $R_t < 1$, then the net nominal interest rate becomes negative, and the representative household can make infinite profits by selling bonds and using the proceeds to accumulate hoards of cash balances. In this case, the household's problem fails to have a well-defined solution. Thus, a fourth and final restriction on the expectations functions ψ^1 and ψ^2 is required:

(R4) For all $(x_1, x_2, ..., x_N) \in \mathbf{R}_{++}^N$ satisfying $x_i \geq \beta$ for all $i = 1, 2, ..., N$, $\psi^1(x_1, x_2, ..., x_N) \geq \beta$ and $\psi^2(x_1, x_2, ..., x_N) \geq \beta$.

Restriction (R4) states that if the monetary authority always chooses a rate of money growth that is greater than or equal to the household's discount factor β, as it must to guarantee that the net nominal interest rate is nonnegative under perfect foresight, then private agents who form their expectations using the functions ψ^1 and ψ^2 will always expect future rates of money growth to greater than or equal to β, so that nominal interest rates will be nonnegative here as well. Thus, when coupled with the constraints

$$x_t \geq \beta \tag{16}$$

for all $t = 0, 1, 2, ...$ imposed on the monetary authority's choice of policy, (R4) performs the role of Marcet and Sargent's (1989) projection facility by insuring

that private expectations remain consistent with the conditions required for the existence of an equilibrium in this model.

Combining (13)-(15), the representative household's consumption and employment are determined in equilibrium as

$$c_t = n_t = \beta\left(\frac{\theta - 1}{\theta}\right)\left[\frac{x_t}{\psi^1(x_{t-1}, x_{t-2}, ..., x_{t-N})}\right]\left[\frac{1}{\psi^2(x_{t-1}, x_{t-2}, ..., x_{t-N})}\right] \quad (17)$$

for all $t = 0, 1, 2, ...$ Thus, the monetary authority chooses a sequence of money growth rates $\{x_t\}_{t=0}^{\infty}$ to maximize the household's utility function (1) subject to the constraints (16) and (17) for all $t = 0, 1, 2, ...,$ taking the initial conditions $x_{-N}, x_{-N+1}, ..., x_{-1}$ as given. Since expectations of future money growth depend only on past rates of actual money growth, the solution to this problem is time-consistent; optimal policy is the same, regardless of whether the monetary authority chooses the entire sequence $\{x_t\}_{t=0}^{\infty}$ at the beginning of period $t = 0$ or whether it chooses each x_t at the beginning of each period $t = 0, 1, 2, ...$ Thus, an equilibrium for this model can be defined as follows:

Definition An *equilibrium* consists of a sequence of money growth rates $\{x_t\}_{t=0}^{\infty}$ that maximizes the representative household's utility function (1) subject to the constraints (16) and (17) for all $t = 0, 1, 2, ...,$ taking the initial

conditions $x_{-N}, x_{-N+1}, ..., x_{-1}$ as given.

Using this definition, part 2 of the appendix establishes

Proposition Let ψ^1 and ψ^2 satisfy (R1)-(R4) and suppose, in addition, that $\beta^N > 1/2$. Then any equilibrium $\{x_t\}_{t=0}^{\infty}$ that converges to a steady state, with

$$\lim_{t \to \infty} x_t = x$$

for some constant x, must have $x = \beta$.

According to the proposition, restrictions (R1)-(R4) guarantee the uniqueness of the model's steady state, provided that agents in the economy are sufficiently patient. In this unique steady state, monetary policy follows the Friedman (1969) rule, contracting the money supply so that the net nominal interest rate $R_t - 1$ is constant and equal to zero. Thus, (R1)-(R4) and $\beta^N > 1/2$ also guarantee that in steady state, optimal monetary policy here is the same as it is in the case, studied by Ireland (1996), where agents have rational expectations and the monetary authority can commit to a policy at the beginning of time. Note that in practice, the extra restriction $\beta^N > 1/2$ is likely to hold. Consider, for example, an annual version of the model, and let $N = 10$, so that it takes ten years for

any policy of constant money growth to become fully credible. Then $\beta^N > 1/2$ requires only that the annual discount factor β exceed $(1/2)^{1/10} = 0.933$.

Two examples illustrate how (R1)-(R4) allow the monetary authority to build credibility for a disinflationary policy when the economy begins away from its unique steady state, with a positive rate of inflation. Both examples use an annual version of the model, with $\beta = 0.95$, $N = 10$, and

$$\psi^1(x_{t-1}, x_{t-2}, ..., x_{t-10}) = \psi^2(x_{t-1}, x_{t-2}, ..., x_{t-10}) = \prod_{j=1}^{10} x_{t-j}^{\alpha_j},$$

so that α_j represents the elasticity of z_t^{t-1} and z_{t+1}^{t-1} with respect to x_{t-j}. Restriction (R1) requires that $\alpha_j \geq 0$ for all $j = 1, 2, ..., 10$, while (R2) requires that

$$\sum_{j=1}^{10} \alpha_j = 1.$$

Equations (8) and (12) imply that $\theta/(\theta - 1)$ measures the steady-state markup of price over marginal cost; both examples set $\theta = 6$, corresponding to a markup of 20 percent. Finally, both examples set $x_{-10} = x_{-9} = ... = x_{-1} = 1.03$, so that the model begins with annual rates of actual and expected inflation equal to 3 percent, approximately the rate of core consumer price inflation in the United States since 1993.

The first example sets $\alpha_j = 0.1$ for all $j = 1, 2, ..., 10$. Table 1 shows that in this case, optimal policy reduces the rate of money growth immediately to its unique steady-state level, so that the equilibrium has $x_t = \beta$ for all $t = 0, 1, 2, ...$ Initially, output and employment fall, as expectations adjust only gradually to the change in policy. Eventually, however, the declining rate of expected inflation allows output to rise. Thus, in this example, the monetary authority builds credibility for its disinflationary policy, as suggested by Taylor (1982) and McCallum (1995), by demonstrating that it will stick to this policy despite the short-run costs.

Table 1

Years	Money Growth (Percent)	Output (Percent Deviation from Initial Steady State)
-10 - -1	+3.00	0.00
0	-5.00	-7.77
1	-5.00	-6.26
2	-5.00	-4.74
3	-5.00	-3.18
4	-5.00	-1.60
5	-5.00	0.00
6	-5.00	+1.63
7	-5.00	+3.29
8	-5.00	+4.97
9	-5.00	+6.68
10 - ∞	-5.00	+8.42

The second example sets $\alpha_j = 0$ for $j = 1, 2, ..., 9$ and $\alpha_{10} = 1$, so that expectations adjust much more slowly to an observed change in policy. Table 2 shows that in this case, optimal policy smooths the short-run costs over time by

taking a gradual approach to disinflation. The equilibrium money growth rate reaches its unique steady-state level, but only after twenty years have passed. Output remains below its initial level for ten years and takes thirty years to completely adjust.

Table 2

Years	Money Growth (Percent)	Output (Percent Deviation from Initial Steady State)
-10 - -1	+3.00	0.00
0 - 9	-1.30	-4.17
10 - 19	-4.01	+1.48
20 - 29	-5.00	+6.20
30 - ∞	-5.00	+8.42

4. Conclusion

Typically, models of time-consistent monetary policy have many equilibria. This multiplicity presents a problem if one chooses to interpret the models along normative lines, for the theory fails to suggest how a central banker who is stuck in a high-inflation equilibrium might steer the economy towards a preferred, low-

inflation equilibrium.

Results derived here suggest that the assumption of rational expectations lies at the source of the multiplicity problem. Under rational expectations, the expected rate of inflation often jumps higher, not only when the monetary authority surprises the public by creating too much inflation, but also when the monetary authority surprises the public by attempting to disinflate. Thus, this paper replaces the rational expectations assumption with a set of alternative restrictions on expectations that allow the monetary authority to build credibility for a disinflationary policy by actually adopting and following that policy for a sufficient length of time. Under these alternative restrictions, the model used here has a unique steady state, in which monetary policy follows the Friedman (1969) rule by contracting the money supply to keep the nominal interest rate constant at zero.

Two examples show that when the economy begins away from this unique steady state, with positive inflation, the monetary authority can successfully disinflate. In both cases, however, the disinflation is accompanied by short-run losses in aggregate output and employment; in the second case, these costs are sufficient to make a gradual approach to disinflation optimal. For central bankers, therefore, the news is both good and bad: credibility can be acquired, but only at a

price.

5. Appendix

5.1. Implications of Household Optimization

During each period $t = 0, 1, 2, ...$, the representative household chooses sequences $\{c^t_{t+j}\}^\infty_{j=0}$, $\{c^t_{t+j}(i)\}^\infty_{j=0}$, $\{n^t_{t+j}\}^\infty_{j=0}$, $\{m^t_{t+j+1}\}^\infty_{j=0}$, and $\{b^t_{t+j+1}\}^\infty_{j=0}$ to maximize its utility function (2) subject to the constraints (3)-(5) for all $j = 0, 1, 2, ...$. When the market-clearing conditions $m^t_{t+j} = 1$ and $b^t_{t+j} = 0$, $j = 0, 1, 2, ...$, are imposed, the first-order conditions for this problem can be written as

$$(c^t_{t+j})^{(1-\theta)/\theta} c^t_{t+j}(i)^{-1/\theta} = (\lambda^t_{t+j} + \mu^t_{t+j}) p^t_{t+j}(i), \tag{A.1}$$

$$1 = \lambda^t_{t+j} w^t_{t+j}, \tag{A.2}$$

$$\lambda^t_{t+j} z^t_{t+j} = \beta(\lambda^t_{t+j+1} + \mu^t_{t+j+1}), \tag{A.3}$$

$$(\lambda^t_{t+j} + \mu^t_{t+j}) z^t_{t+j} = \beta R^t_{t+j} (\lambda^t_{t+j+1} + \mu^t_{t+j+1}), \tag{A.4}$$

$$\left[\int_0^1 c^t_{t+j}(i)^{(\theta-1)/\theta} di\right]^{\theta/(\theta-1)} = c^t_{t+j}, \tag{A.5}$$

and

$$z_{t+j}^t = \int_0^1 p_{t+j}^t(i)c_{t+j}^t(i)di \tag{A.6}$$

for all $j = 0, 1, 2, ...$, where $\lambda_{t+j}^t > 0$ and $\mu_{t+j}^t \geq 0$ are multipliers on the budget constraint (4) and the cash-in-advance constraint (5) and where the cash-in-advance constraint is assumed to hold with equality even when it does not bind.

Multiplying both sides of (A.1) by $c_{t+j}^t(i)$, integrating over $i \in [0, 1]$, and using (A.5) and (A.6) yields

$$\lambda_{t+j}^t + \mu_{t+j}^t = 1/z_{t+j}^t. \tag{A.7}$$

Substituting this result back into (A.1), raising both sides to the power $1 - \theta$, integrating over $i \in [0, 1]$, and using (A.5) and the definition

$$p_{t+j}^t = \left[\int_0^1 p_{t+j}^t(i)^{1-\theta}di\right]^{1/(1-\theta)} \tag{A.8}$$

yields

$$c_{t+j}^t = z_{t+j}^t/p_{t+j}^t. \tag{A.9}$$

Equations (A.8) and (A.9), with $j = 0$, coincide with (10) and (7) in the text

Substituting (A.7) and (A.9) into (A.1), solving for $c_{t+j}^t(i)$, and setting $j = 0$ yields (6) in the text. Substituting (A.3) and (A.7) into (A.2), solving for w_{t+j}^t,

and setting $j = 0$ yields (8) in the text. Finally, substituting (A.7) into (A.4), solving for R^t_{t+j}, and setting $j = 0$ yields (9) in the text.

5.2. Proof of Proposition

The following lemma proves useful in establishing the main result:

Lemma Let $f : \mathbf{R}^N_{++} \rightarrow \mathbf{R}_{++}$ be a differentiable function satisfying

$$f(x, x, ..., x) = x$$

for all $x \in \mathbf{R}_{++}$. Then

$$\sum_{j=1}^{N} f_j(x, x, .., x) = 1$$

for all $x \in \mathbf{R}_{++}$, where f_j denotes the partial derivative of f with respect to its jth argument.

Proof Follows from Apostol's (1974, pp.346-8) Definition 12.2 and Theorem 12.5.

In equilibrium, the monetary authority chooses the sequence $\{x_t\}_{t=0}^{\infty}$ to maximize the representative household's utility function (1) subject to the constraints (16) and (17) for all $t = 0, 1, 2, ...$, taking the initial conditions $x_{-N}, x_{-N+1}, ..., x_{-1}$ as given. Since, by (R2) and (R3), the expectations functions ψ^1 and ψ^2 are

continuously differentiable and satisfy $\psi^1(x, x, ..., x) = \psi^2(x, x, ..., x) = x$ for all $x \in \mathbf{R}_{++}$, the first-order condition for this problem implies that if the solution has

$$\lim_{t\to\infty} x_t = x,$$

then the constant x must satisfy

$$x\varphi = \left[1 - \left(\frac{\theta - 1}{\theta}\right)\left(\frac{\beta}{x}\right)\right]\left\{\sum_{j=1}^{N} \beta^j \left[\psi_j^1(x, x, ..., x) + \psi_j^2(x, x, ..., x)\right] - 1\right\}, \quad \text{(A.10)}$$

where the φ denotes the limit of the sequence $\{\varphi_t\}_{t=0}^{\infty}$ of multipliers on the constraints $x_t \geq \beta$, $t = 0, 1, 2, ...$ In addition, x and φ must satisfy the complementary slackness conditions $\varphi \geq 0$, $x \geq \beta$, and $\varphi(x - \beta) = 0$.

Since $x \geq \beta$ and $\theta > 1$, it must be that

$$1 - \left(\frac{\theta - 1}{\theta}\right)\left(\frac{\beta}{x}\right) > 0.$$

Moreover,

$$\begin{aligned} & \sum_{j=1}^{N} \beta^j \left[\psi_j^1(x, x, ..., x) + \psi_j^2(x, x, ..., x)\right] \\ \geq\ & \beta^N \sum_{j=1}^{N} \left[\psi_j^1(x, x, ..., x) + \psi_j^2(x, x, ..., x)\right] = 2\beta^N, \end{aligned}$$

where the first inequality follows from (R1) and the second equality follows from (R2) and the lemma. Thus, when $\beta^N > 1/2$, (A.10) requires that $\varphi > 0$ and $x = \beta$.
